F Simulation module labview Simulation module labview. Download Simulation module labview. The simulation module lets you create and debug simulations. For more information, see Create a simulation. You can also write application code that you call from the simulation. Simulation modules include the simulation run control, analysis tools, and support library. LabVIEW simulation module There is a lot that is involved in making a successful simulation. You have to define all parts of the simulation, including the definition of simulation data and start and stop conditions. Components The simulation module requires simulation components, a motion control device driver, and the runtime library. Simulation components include: Simulation runtime library. The runtime library tells the simulation module when a simulation starts and stops. Device driver. The device driver controls the I/O ports of a device. For example, it can control joysticks and keyboards. Simulation run control. The run control is a software system that runs a simulation. For information about the simulation components, see Device drivers, and Run control. Configuration A simulation module includes configuration information that you can edit. You can edit configuration information for each simulation component. Another example of a simulation component is the motion control device driver. The motion control device driver provides a common interface for all external I/O devices. The configuration editor lets you edit simulation component, simulation runtime library, and simulation runtime library configurations. The configuration window shows the simulation component, simulation runtime library, and simulation runtime library configurations. You can change configuration information by clicking the configuration nodes. You can set the simulation run control to run the simulation when you quit LabVIEW. The simulation module uses the runtime library for timing and other functions. The run control must start the runtime library before it can start the simulation. You can use the run control to start the runtime library. The simulation module starts or stops a simulation with the simulation run control. The simulation run control starts the simulation based on the simulation start condition. The simulation run control stops the simulation when it is ready to exit. Example 1. 1 To simulate a motor that turns the direction of a shaft, first build a simulation using the motor as an I/O device. Then add an analysis module that checks whether the shaft turns at the speed you want. 2 Open the simulation by using the Start Simulation button. 3 To simulate a motor, add an I/O Module. Use the ■ I/O → Digital f678ea9f9e
